

# Comments on Security

P.B. Ladkin

Use of resources requires

Responsibility:

Users adhere to *conventions* of use

Conventions may be

- legal
- contractual
- social

Accountability:

Actions and states (data, permissions)  
are attributable to individuals

*Data* is

- file contents
- message contents

*Permissions* are

- who may read
- who may write
- who may act

## Examples

### Obligations:

Legal	don't threaten others don't impersonate others ? don't hinder others' work ?
Contractual	don't play games don't write personal letters keep business contracts private
Social	porno to be read-protected don't read others' mail

Access	to data	(files, messages, infoflow)
	to state	(system state)
	to actions	(read, write, do)

Access control:

Responsible group

Permitted group

Unix:

everything is a 'file'

*responsible* = *user*

*permitted* = system-defined group  
+ '*superuser*'

*actions* = read, write, do

Accountability:

User + Superuser

*Superuser* can do anything

Much system data only writeable by superuser

Some system data only readable by superuser

Authentication follows *public-key* scheme

(although public-key identified after Unix built)

Key management under user control

Problem:

users need to perform certain sysoperations

Example:

public keys contained in one file, */etc/passwd*

Authentication easy: compare  $E(K, \text{passwd})$

with that in */etc/passwd*

however:

Key management requires user to write */etc/passwd*  
so either

- all users must have write access
- or users must 'spoof' *superuser*

First option infeasible

(users may write others' passwords,  
achieving *denial of service*)

Second option taken: *setuid* command

Potential security hole:

a malicious user runs arbitrary processes

- after a process has executed *setuid(root)*
- before it has executed *setuid(user)*

Problem:

- there is only one level of privilege: *do all*
- programs which *setuid* are not provably secure

Alternative design options:

- important control files individual to permit-group
- different security levels for services
- no pervasive trusted-user privilege
- rigorous trusted-user authentication
- no ID change mechanism

## Internet communication problems

- keys sent in cleartext: vulnerable to
  - physical snooping
  - system holes allowing user snooping
- E-mail not reliably authenticated
- denial of service
- nuisance communication
- local breaking and entering
- masquerading

These were not problems when

- nets were physically secure
- privileged users
  - could be identified
  - could be trusted
  - configured trusted mail
  - controlled authentication

Encryption of restricted information solves many of these problems: for example

Channel communication via tunnelling

Tunnelling requires encryption after **X**

$$M \mapsto E(K, M)$$

and decryption before **Y**

$$EM \mapsto D(K', EM)$$

where  $D(K', E(K, M)) = M$

## Encryption Functions $E$ , $D$

### Capability:

$E(K, M) \mapsto \langle K, M \rangle$  hard

$D(K', EM) \mapsto \langle K', EM \rangle$  hard

That is,  $E$  and  $D$  are *one-way*

### Feasibility:

$K, M \mapsto E(K, M)$  should be easy

$K', EM \mapsto D(K', EM)$  should be easy

### Secrecy:

$E(K, M) \mapsto M$  should be hard

$D(K', EM) \mapsto K'$  should be hard, for every  $EM$

### Authenticity:

$E(K, M) \mapsto K$  should be hard, for every  $M$

$D(K', EM) \mapsto EM$  should be hard

## One-key Systems

Capability + Feasibility + ( $K = K'$ )

*If  $K$  known,*

$E(K, M) \mapsto K$  easy

$D(K, EM) \mapsto K$  easy

Consequently

No Secrecy

No Authenticity

*If  $K$  not known,*

$E(K, M) \mapsto K$  hard

$D(K, EM) \mapsto K$  hard

Consequently

Secrecy

Authenticity

Conclusion:

good for *single user* protection

not good for *multi-way* (how is  $K$  shared?)

## Policies

### Mail:

Message contents should generally be secret

Signatures should generally be authentic

### Other Transactions:

Generally secret and obscure

## Two-key Systems

Diffie-Hellmann 1976: public-key encryption

good for multiway, e.g., communication

Capability + Feasibility + ( $K \neq K'$ )

Secrecy:

$K$  public,  $K'$  private

$M \mapsto E(K, M)$  easy

$EM \mapsto D(K', EM)$  hard

Sending easy, receiving hard

Authenticity:

$K$  private,  $K'$  public

$M \mapsto E(K, M)$  hard

$EM \mapsto D(K', EM)$  easy

sending hard, receiving easy

Everyone has both private and public keys

## The Social Dimension of Cyberthreats

Hazard - system state that, in concert with certain (worst case) environmental conditions, leads inevitably (Leveson) to an accident

Accident - undesired, unplanned (not necessarily unexpected) event resulting in a specified level of loss

Threat - similar to hazard but *intentional*

Technically, there's little to choose between threat and hazard

Socially, there is a world of difference

There are technical consequences, however

Intentional threats are **persistent**

Intentional threats are **goal-seeking**  
(teleological)

See Searle, *The Construction of Social Reality*  
for the 'technical' construction of social conventions.

To counter cyberthreats we need to know:

what is the *intention*?

what are the *social conventions*?

how are these conventions implemented?  
(technically, socially)

we then want to limit system behavior which  
leads to **persistent, teleological accidents**

Can it be done?

Lots of social institutions don't fail in quite as disastrous a manner as automated, networked institutions.

What's the difference?

Adherence to convention, encouraged by **accountability**

We 'technical' experts seem to be weak on the implementation of accountability, as well as on other social features. I would suggest that that's where we need to focus
